KEYWORDS: Intergenerational Mobility; Volatility; Economic Risk; Educational Attainment; Early Human Capital Investment.

Abstract: Using data linked across generations in the Panel Study of Income Dynamics, I estimate the relationship between exposure to volatile income during childhood and a set of socioeconomic outcomes in adulthood. The empirical framework is an augmented intergenerational income mobility model that includes controls for income volatility. I measure income volatility at the family level in two ways. First, instability as measured by squared deviations around a family-specific mean, and then as percent changes of 25% or more. Volatility enters the model both separately and interacted with income level. I find that family income volatility during childhood has a modest negative association with educational attainment. Volatility has a smaller descriptive role in explaining intergenerational outcomes relative to permanent income. Across the income distribution, the negative association between volatility exposure and educational attainment is largest for young adults from moderate income families.

Introduction

Income volatility in the United States has been on the rise since the 1970's, increasing by at least one-third (Dynan et al. 2012; Gottschalk and Moffitt 1994; Haider 2001; Keys 2008; Ziliak et al. 2011). Driven largely by earnings, it exhibits cyclical behavior (Dahl et al. 2011) and is attributed to both short-term economic shocks and permanent structural change throughout the economy (Gottschalk and Moffitt 2009). Several studies focus on specific examples of volatility, finding that health shocks, workplace injury, divorce, plant closings, and job loss can have long term effects on adults (Charles and Stephens 2004; Currie et al. 2010; Eliason and Storrie 2007; Huff Stevens 1997; Woock 2009). Job losses may reduce achievement and educational attainment among children (Coelli 2009; Huff Stevens and Schaller 2011; Johnson et al. 2012), but it is unclear whether this effect is driven by volatile income or unobservable circumstances among the jobless. While the literature does confirm that growing up in poverty is associated with lower education, earnings, and cognitive ability (Dahl and Lochner 2012; Duncan and Brooks-Gunn 2000; Duncan et al. 2008), we do not know if growing up in households with unstable incomes per se warrants concern.

Research examining the long term consequences of volatility is lacking. Most volatility research has, up to this point, focused on trends, statistical measurement, and the implications such measures have when interpreting changes in income inequality in the United States (Burkhauser and Couch 2009). Although the literature relating income to long term outcomes and mobility mainly focuses on measured levels, not volatility, these studies help explain income's socioeconomic correlates. Studies identify a connection between early childhood

poverty, and lowered education, earnings and receipt of public assistance as an adult (Duncan et al. 1994; Duncan et al. 2008; Duncan et al. 2011; Magnuson and Votruba-Drzal 2009; Mazumder and Davis 2012). One channel enabling such relationships across generations may be human capital (Becker and Tomes 1979; Blau 1999; Haveman et al. 2010; Lillard and Willis 1994; Ludwig and Miller 2007). This paper therefore draws motivation from a model of mobility where parental income determines human capital for children in the household, which then largely determines the children's educational attainment, adult earnings, income, and well-being (Becker and Tomes 1979). Work on early human capital formation describes how initial skills are necessary to acquire additional skills in the future (Cunha et al. 2005), and modest, positive associations exist between income and educational attainment (Duncan et al. 2008), and performance on math and reading assessments (Dahl and Lochner 2012). Such skill deficits may drive findings in studies estimating intergenerational relationships.

In this paper I examine the long-term consequences of income volatility during childhood on subsequent adult outcomes. There has been extensive evidence on intergenerational economic mobility in earnings, income, education, and wealth (Becker and Tomes 1979; Black et al. 2005; Charles and Hurst 2003; Chetty et al. 2014; Mazumder 2005; Meghir and Palme 2005; Solon 1992; Zimmerman 1992). The mobility model adopted here augments the standard intergenerational income elasticity (IGE) model to include income volatility and then extends the model to include educational outcomes. Mechanisms giving rise to the intergenerational transmission of volatility in the standard Becker and Tomes (1979) framework are discussed, including human capital investment decisions of parents with volatile income amid imperfect capital markets (Loury 1981; Mazumder 2005). Becker and Tomes (1986) emphasize the role of

functioning capital markets within intergenerational models, and in this context imperfections within such markets imply that income shocks can persist. Part of this persistence may include a range of consequences from events related to income volatility impacting child learning and development (Hill et al. 2013), perhaps less likely to be addressed by households with costlier or otherwise constrained access to loanable funds. The emphasis on adult educational attainment along with adult income reinforces the importance of human capital as a determinant of socio-economic outcomes, including income over the lifecycle. By accounting for income shocks during childhood, this paper addresses a missing component in the literature on the transmission of mobility.

To empirically implement the model I link families in the Panel Study of Income Dynamics (PSID) across generations from 1970-2007. Income volatility during childhood is defined as the volatility of natural log family income from labor market earnings, total taxable non-labor income, and government transfers between ages 0 and 16. For each person, volatility is calculated in two ways. First, I decompose residual total volatility into its permanent and transitory components and isolate the transitory measure as an explanatory variable (Gottschalk and Moffitt 1994; 2009). Prior to the log transformation, I residualize income by regressing family income on an age quartic for the household head. A second measure then estimates volatility as the number of between-year income shifts of 25% or more (25% +) (Dahl et al. 2011). With both approaches volatility enters the model separately and interacted with income level.

I examine income level and educational attainment for adults who, as children, grew up in households with varying incidence of income volatility. Adult income is measured at age 25 and beyond, and educational attainment is measured both by whether the child drops out of high school and whether they attain post high school education near the age threshold of 25 using a linear dependent variable model. The OLS classical errors-in-variables assumption is violated in the income IGE models, as families with higher lifetime mean income typically experience relatively higher rates of income growth over the lifecycle. This leads to intergenerational income estimates that are too low if second generation income is recorded while primary earners are in early adulthood and too high as workers approach older age. To address this, the income IGE models account for lifecycle earnings growth and adopt specifications found to minimize left-side measurement error in second generation incomes (Haider and Solon 2006; Lee and Solon 2009).

Using two measures of volatility, I find that income volatility exposure during childhood is associated with lower educational attainment, though the magnitude of this association is modest relative to permanent income. The association is larger among adults from moderate income backgrounds where, for example, a 1 standard deviation increase in transitory volatility translates to a lower likelihood of post high school attainment by approximately 5%, relative to a 2-3% lower likelihood of post high school education evaluated at the mean. To properly measure volatility over time, I exclude observations that do not contain at least 15 of 16 childhood years. At the same time, this reduces the size of the sample, which may have efficiency implications for intergenerational empirical models with small sample sizes, especially those examining volatility across the income distribution.

Background

While relatively little work exists on the intergenerational aspects of volatility, the inheritability of socio-economic status is well documented in the literature on intergenerational transmission (Altonji and Dunn 2000; Charles and Hurst 2003; Solon 1992; Zimmerman 1992). The intergenerational mobility model posits that parental endowments and investments in child human capital largely determine adult offspring socioeconomic outcomes (Becker and Tomes 1979, 1986; Solon 1999) such as income, earnings, and education (Blanden, Gregg, and Machin 2005; Blau 1999; Bloome & Western 2011; Ermish & Pronzato 2011; Guldi, Page, and Stevens 2007; Oreopoulos, Page, and Stevens 2006). Parental income supports investment in child human capital, implying that transitory shocks to income potentially alter the level or timing of such investment. Because human capital formation drives educational attainment, which in turn influences lifetime income via labor market earnings (Polachek 2008), the empirical model explores the link between volatility and both adult income and adult educational attainment.

As described above, human capital is a primary mechanism underlying the linear relationship between the income level or socioeconomic status $y_{i,g-1}^{parent}$ of working-age parents with children in generation g-1 and the adult income level y_{ig}^{child} of their adult offspring *i* in generation g:

$$y_{ig}^{child} = \alpha + \beta y_{i,g-1}^{parent} + \varepsilon_{ig}. \quad (1)$$

Total parental income in childhood generation g-1, $y_{i,g-1}^{parent}$, can be decomposed into a permanent income component $\mu_{i,g-1}^{parent}$ and a transitory income component $v_{i,g-1}^{parent}$ (Gottschalk and Moffitt 1994):

$$y_{i,g-1}^{parent} = \mu_{i,g-1}^{parent} + v_{i,g-1}^{parent} = C_{i,g-1}^{parent} + I_{i,g-1}^{child}. \quad (2)$$

Parental income in generation g-1 is spent on parental consumption $C_{i,g-1}^{parent}$ and investment in child human capital $I_{i,g-1}^{child}$. As shown in Eq. (2), shocks or variation in $v_{i,g-1}^{parent}$ *could* impact investment in children's human capital $I_{i,g-1}^{child}$ if families lack sufficient precautionary savings and also under imperfect credit markets, allowing volatility to enter the intergenerational model. Equations (1) and (2) are adapted from work by Solon (2004), which provides a more formal and extensive modeling of intergenerational mobility.

The empirical mobility model is a log-linear transformation of Eq. 1, regressing log adult offspring income on the log income of working-age parent(s) (Solon 1999):

$$ln y_{ig}^{child} = \alpha + \beta ln \bar{y}_{i,g-1}^{parent} + \varepsilon_{ig}, \quad (3)$$

where y_{ig}^{child} represents yearly adult offspring income in period or generation *g* and $\bar{y}_{i,g-1}^{parent}$ is the mean income of the working-age parent(s) in period *g-1*, during childhood years of the offspring. β denotes the IGE, measured with a white noise error ε_{ig} (Zimmerman 1992). The IGE summarizes the relationship between income, earnings, or wealth across generations. An IGE of 1 denotes no mobility across generations and a value of 0 denotes perfect mobility, and, by design, known causal factors are omitted in the regressions (Becker and Tomes 1986). Studies estimating IGE's account for lifecycle effects and measurement error using longer measures of permanent earnings or incomes, with IGE estimates ranging between 0.4 and 0.6 (Gouskova et al. 2010a; Mazumder 2005; Solon 1992; Zimmerman 1992). The optimizing decisions of parents with respect to their own consumption and human capital investment into offspring represent structural parameters underlying the reduced-form empirical mobility model

specification as described in Eq. (1) and (3). These parameters include a decomposed definition of family income that recognizes the role of income fluctuations in determining adult outcomes.

Like the IGE, volatility is a summary measure capturing events that add and take away income. While measures of income and earnings volatility have seldom been used in an explanatory context, a variety of event studies have documented specific examples of economic volatility. This work attempts to explain the role of job loss and income shocks in predicting earnings (Oreopolous et al. 2008), health (Eliason and Storrie 2007; Ruhm 2005), marriage, and divorce (Charles and Stephens 2004; Conger et al. 1990; Eliason 2012; Hankins and Hoekstra 2011; Mayer 1997; Nunley and Seals 2010). For children, volatility by way of job loss may lead to lowered educational attainment and achievement, and behavioral problems (Coelli 2009; Huff Stevens and Schaller 2011; Johnson et al. 2012), and this may be especially true for lower-income children whose families are unable to buffer such shocks (Page et al. 2009).

Volatility measures capture these types of income shocks experienced within families. As shown below, the *t* subscript in (4) denotes individual years *within* time period or generation g-1 (e.g., youth). Similar to Eq. 2, though now for family *i* in year *t* within generation g-1, I decompose the log of annual family income lny_{it} into a permanent component μ_i and a transitory component v_{it}:

$$lny_{it} = \alpha_t \mu_i + \varphi_t v_{it}, \tag{4}$$

where μ_i is permanent income, v_{it} is transitory income, and α_t and φ_t are time-varying factor loadings on the permanent and transitory components. Assuming independence of the permanent and transitory components and that factor loadings equal 1 in all years, the variance of log income in (4) is

$$Var(lny_{it}) = \sigma_{\mu_i}^2 + \sigma_{v_i}^2. \quad (5)$$

The decomposition in Eq. (5) differentiates between permanent volatility ($\sigma_{\mu_i}^2$) attributable to longer-term or structural income shifts and transitory volatility ($\sigma_{v_i}^2$) related to short-term events (Gottschalk and Moffitt 2009; Ziliak et al. 2011). Transitory volatility, a measure used in this study, is defined by yearly deviations $y_{it} - \bar{y}_i$ from mean (parental) income $\bar{y}_i$ specific to family *i* as measured over the first 16 years of the child's life T_i:

$$Transitory\ Volatility = \ \text{var}(v_i) = \sigma_{v_i}^2 = (\tfrac{1}{T_i - 1}) \sum_{t=1}^{T_i=16} (y_{it} - \bar{y}_i)^2. \quad (6)$$

Transitory volatility might approximate risk due to temporary increases in economic hardship consistent with adverse events such as job loss, injury, divorce, or declining health, but could equally result from voluntary or positive events including bonus or incentive pay (Dynan et al. 2012). A leading explanation for permanent volatility is skill biased technological change (Autor, Kearney, and Katz 2008), whereby structural changes in the economy put a higher premium on skilled labor reflected by greater income and earnings inequality throughout society (Gottschalk and Moffitt 2009). Total volatility measures combine transitory and permanent components with fewer assumptions. Hardy and Ziliak (2014), Ziliak et al. (2011), Dahl et al. (2011), and Dynan et al. (2012) measure total volatility with the percent change or close transformations, such as the standard deviation of income percent changes. In this study, I follow Dahl et al. (2011) and define total volatility for each child-family observation *i* as the sum of the number of year-over-year percent changes in family (parental) income greater than or equal to 25% throughout the first 16 years of the child's life over *N* observations:

$$Total\ Volatility = \sum_{i=1}^{i=N} \sum_{t=1}^{T_i=16} \left(1 \middle| 100 * \tfrac{y_{it} - y_{it-1}}{\text{Y}_{\text{average}}} \geq 25, 0\ otherwise\right), \quad (7)$$

where $Y_{average} = (Y_t+Y_{t-1})/2$. Results using transitory and total measures of volatility comport with respect to statistical significance and direction, though the magnitude of the descriptive relationship is sensitive to the choice of measure.

Several studies document rising earnings and income volatility income over the past 30 to 40 years (Dynan et al. 2012; Gottschalk and Moffitt 1994, 2009; Ziliak et al. 2011), and socio-economic subgroups with lower education levels and lower earnings exhibit relatively higher levels of volatility (Gottschalk and Moffitt 1994; Keys 2008; Ziliak et al. 2011). If family income volatility during childhood is related to adult outcomes, intergenerational data sources such as the PSID provide useful socio-economic outcomes for adults who were children during the 1970's and 1980's, periods of rising volatility. Shore (2012) and Dohmen et al. (2012) take such an approach, using panel data and concluding that parental income volatility leads to adult offspring income volatility, with volatility as a proxy for the transmission of risk from parents to children. I follow Shore (2012) in using the PSID to understand how higher income moments of parental income transmit onto offspring, with a focus on income and education levels among adult offspring born before 1983. Prior to Shore (2012) income shocks have typically been described as a measurement problem to overcome in explaining permanent income (Blau 1999; Duncan 1988) or assumed to be mean zero over time (Becker and Tomes 1979). Thus the introduction of volatility approximating for such shocks, as an explanatory variable in empirical mobility models, is rare up to this point.

Volatility and Intergenerational Mobility

Empirical intergenerational mobility models assume that income volatility has no role in predicting income mobility. This is supported largely by the permanent income hypothesis, wherein households borrow against negative transitory income shocks by accessing perfectly functioning capital markets and/or savings, while saving positive transitory income shocks. Yet there are reasons to expect that income variance measures like volatility transmit across generations. Constant relative risk aversion utility models of family consumption and saving accounting for prudence (i.e. precautionary savings) by decision makers underscore the role of income variances in determining optimal choices. In these models, rising variability of income affects consumption, human capital investment, and utility, possibly reducing parental human capital investment in children (Attanasio and Weber 2010).

Statistically, transitory shocks persist over several years (Hyslop 2001), and both permanent and transitory shocks contribute substantially to measured inequality (Gottschalk and Moffitt 1994). The timing of these shocks, possibly during early human capital formation, may bring on harmful stressors at important stages of child development where basic skills and attitudes are being formed. These initial skills allow for the development of more complex skills, attitudes, coping mechanisms, and problem solving techniques later in childhood and into adulthood, which may largely determine educational attainment and income (Cuhna et al. 2005; Hill et al. 2013; Lochner and Monge-Naranjo 2012). Other forms of income volatility may instead reflect income growth and intra-generational upward mobility, and therefore support educational and developmental investments in children. For example, pay raises or a profitable business venture within a family represent a wider set of investment possibilities benefiting

children. Still, uncertainty from variable year-over-year income growth may nonetheless lower investments in children.

The early child development consequences listed above may occur due to the possibility of imperfect capital markets and constrained access to loanable funds. Early theory on mobility recognized that parents may be denied loans or credit cards that allow for consumption smoothing against negative income shocks. In the event of such denials or market imperfections, income shocks might reduce investments in children (Becker and Tomes 1986; Loury 1981; Mazumder 2005; Lochner and Monge-Naranjo 2012), a final motivation for the inclusion of transitory income shocks in an intergenerational empirical model. Imperfections of several kinds arise in this market, as future ability or income of the child investment is noisy to predict, but necessary to justify investment. If collateralized through a child borrower, a loan for human capital investment amounts to indentured servitude and cannot legally or realistically occur (Becker and Tomes 1986; Kane and Ellwood 2000). For example, Rothstein and Wozny (2013) at once describe the human capital investment decisions of parents as a function of permanent income while acknowledging the negative impact of credit constraints amid economic uncertainty on parental human capital investment decisions.

Previous empirical intergenerational models relying on the permanent income hypothesis to justify omitting higher income moments seem to exclude an important component of the family's utility maximization process. I therefore adapt the mobility model in Eq. 3 to include shocks from income volatility. I then depart from the standard IGE model by substituting adult educational attainment for income as a dependent variable. In so doing I follow empirical work by Oreopoulos et al. (2006), Hertz et al. (2007), and Pronzoto (2010), and the theoretical insights

of Becker and Tomes (1979; 1986) and Mincer (1974) emphasizing the importance of human capital for an array of intra and inter-generational labor market and social outcomes. Thus, the reduced-form intergenerational mobility models in Eq. (1) and Eq. (3) are augmented to include income volatility, $V_{i,g-1}^{parent}$:

$$O_{ig}^{child} = \alpha + \beta y_{i,g-1}^{parent} + \gamma V_{i,g-1}^{parent} + \varepsilon. \quad (8)$$

Moving forward, Eq. (8) is the basic augmented intergenerational mobility model, inclusive of adult income and educational attainment outcomes O_{ig}^{child} estimated throughout the paper. The mobility model allows for the possibility that volatility has an intergenerational relationship to income and well-being, in which case γ is non-zero. Through the mechanism of human capital investment by parents, volatility is theoretically associated with higher overall volatility of human capital investment, which supports the inclusion of higher income moments empirically.

Empirical Model: The Association between Volatility and Adult Outcomes

Holding the level of family income during childhood constant, I estimate the relationship between family income volatility during childhood $V_{i,g-1}^{parent}$ and a set of adult outcomes O_{ig}^{child} which parents plausibly seek to maximize in their children (Becker and Tomes 1979; Haveman et al. 2010). For each adult individual *i*, I estimate the following model via OLS to determine if shocks are transmitted across generations:

$$O_{ig} = \alpha + \beta \overline{I_{0-16_i}} + \gamma V_{0-16_i} + \mathbf{X}\delta + \varepsilon_i. \quad (9)$$

When outcome O_{ig} is adult offspring income, Eq. (9) yields the income IGE for offspring aged 25 and older. It is the canonical intergenerational elasticity model (Gouskova et al. 2010a; Grawe 2006; Lee and Solon 2009; Mazumder 2005; Solon 1992) estimated with controls for income volatility during childhood years 0-16 in generation g-1. Non-income outcomes O_{ig} for high school dropout and post secondary educational attainment are tested in (9) using an OLS binary linear probability model. During childhood years 0-16, mean family income $\overline{I_{0-16_i}}$ is an approximation for permanent income.[1] Family income is defined as the income, earnings, and transfers received in person i's household. To account for potential non linearities in mean income and income volatility, I use a natural logarithmic transformation of family income for parents as well as adult offspring. Educational outcomes are estimated based upon the highest level of education attained by age 26 for respondents who are at least 24 years old, selected to approximate smoothed results for 25 year old adults. The separability of income and volatility is tested via interactions of the two variables. A vector of demographic **X**'s includes age A_i and race of parent, gender of offspring, education of parents, the number of siblings, and whether parents are continuously married. Education is a 0/1 variable equal to one if either parent attends college for four or more years. Age of the household head, A_i, most often the father, is averaged over the observed childhood years of the offspring.

Properly accounting for life-cycle earnings profiles is important, as both earnings and income are known to follow a concave growth profile over prime age working years (Weiss 1986). In the volatility literature, life-cycle effects are often accounted for by replacing income

[1] In unpublished results, I use an alternative specification substituting parental education for family income during childhood. The results are robust to this alternative specification.

with residuals from a regression of income on an age quartic (Gundersen and Ziliak 2008). For intergenerational studies, such effects are modeled with an age quartic within the set of explanatory variables. For estimates of transitory volatility, V_{0-16_i}, I combine both approaches, using an age quartic of household head's average age A_i in the set of demographic variables while estimating volatility using residuals purging lifecycle effects. For percent change volatility, V_{0-16_i}, I elect to follow the intergenerational literature and rely on the age quartic controls to pick up lifecycle effects.

Income IGE models include an age quartic for offspring age interacted with mean family income during childhood. For income elasticity models in (9), the offspring's age equals year *t* minus birth year *b* minus 40, *t-b-40*, normalizing so that offspring age equals zero at age 40. This has the useful feature of simplifying the interpretation of intergenerational elasticities at age 40, where several recent studies recommend evaluating the IGE to minimize bias in estimates of permanent income (Haider and Solon 2006; Lee and Solon 2009).

The estimation of intergenerational models, where the same individuals are followed over time, produces positive autocorrelation of the individual specific error terms over the panel. At the same time, the errors likely have unequal variances, violating the OLS assumption of identical, independently distributed errors. This implies the OLS standard errors are no longer consistent. To address this, the estimates are corrected for heteroscedasticity using Huber-White corrected standard errors, and they are clustered on a unique identifier for each child observation to account for autocorrelation.

Data

The PSID is a longitudinal survey that began in 1968. It consists of two independent samples, the Survey Research Center (SRC) sample and the Survey of Economic Opportunity (SEO) sample. Due to challenges in the SEO survey design, this paper uses the SRC sample of the PSID (Shin and Solon 2011). The PSID collects detailed economic, social, and demographic information on 1968 participant families and their descendants. Over time, offspring of the families are followed as they age and begin their own families, resulting in a sample spanning multiple generations (Institute for Social Research 2006). Major changes in the collection of the PSID throughout the 1990's include a switch to biennial interviews in 1997 and a doubling in the length of interviews between 1995 and 1999 (Gouskova et al. 2010b).

To construct the intergenerational sample, I use the Family Identification and Mapping System from the PSID, which links parents and offspring. Unique individual identifiers and yearly family interview numbers, along with demographic variables for age and marital status, indicate when offspring leave their childhood family units. The main income measure, family money income, can be tracked for offspring over the lifecycle. Individuals are observed as dependent children within families, though most of the information collected applies to adults. As subjects enter adulthood they participate in the PSID survey. The resulting panel is unbalanced since, depending on the age of the subject, there are a range of data on adult income and earnings.

The data file I construct consists of 1,070 adult observations in transitory and 25% + total volatility models of education attainment and adult income IGE empirical models, using PSID data from 1970-2007. In an effort to construct comparable samples between the income IGE

models and adult education models, I restrict the estimating sample for educational outcomes models to those with non-missing values of adult offspring log income, and likewise restrict the income IGE models to only allow observations with non-missing adult offspring education. Accordingly, the summary statistics in Table 1 reflect the condition within the estimating models excluding sample respondents reporting missing values of log income, volatility, education, or demographics. Importantly, for both income IGE and educational attainment models I impose the restriction of retaining observations where complete data exist for at least 15 observations over the first 16 years of the child's life. By dropping child-family pairs where several years of data are missing, I aim to avoid a potential attenuation bias in the results and generate accurate estimates of year-over-year income volatility. Missing income data potentially impart a downward bias on the association between volatility and adult outcomes. For example, parents with several years of missing income may erroneously be assigned a high volatility value when in fact the true income process between years is smoother than the missing data reflect. Indeed, unpublished results allowing for a minimum of 3 observations, with at least one observation across three defined child developmental stages ("0-5," "6-10," and "11-16 years old"), suggest that the importance of volatility is attenuated following this approach.[2] To construct the sample for educational outcomes (Tables 3-6), I collapse the data using unique identifiers for each offspring observation and retain relevant fixed data on income and demographic characteristics for child-family observations, exploiting variation between observations to identify the

[2] In unpublished results, I also analyze the association between income volatility during childhood and adult educational outcomes for persons between ages 29 and 31. After retaining observations containing 15 of 16 childhood years, the sample falls to 645 observations. The general results are consistent across models with respect to both statistical significance and direction of the relationships in question, though in some instances the magnitudes differ. I therefore elect to focus the discussion on results for 25 year old adults.

descriptive relationship between volatility and adult outcomes. All together this reduces the sample to 1,070 unique offspring observations.

Family money income, the main income measure used, is a summary measure of earnings and income for all members of the family. As described earlier, it is the summation of total taxable income, non-taxable transfer income, and social security income for the head (husband), wife, and other members of the family. Families, as defined by the PSID, include cohabitating adults and single individuals living alone in a distinct household. When the mother and father are both present, fathers are automatically assigned head status. The PSID assigns a family income value for all persons in a family based on the family interview number. As such, I have family income for mothers, fathers, heads of household, and offspring. As with previous work on income volatility and dynamics, I address changes in the collection of PSID income and earnings data by imposing a consistent topcoding and bottomcoding strategy. The top 1% of family income (Shin and Solon 2011) is excluded, and I assign a value of $1 to family incomes of zero and below (Dynan et al. 2012).[3]

Figure 1 depicts transitory income volatility trends using a 3 year and 9 year moving average between 1975 and 1995, adjusted for family size. These are crucial years in which many sample respondent children are potentially exposed to instability incurred by working-age parents. From the late 1970's through 1995, family income volatility rises 25% for the 9 year moving average of transitory income volatility. This is consistent with a nearly 36% increase in volatility described in Dynan et al. (2012), a 15% increase in earnings volatility between the

[3] Before 1979, the topcode value of income was $99,999, by 1980 it is $999,999, and in 1981 it increases to $9,999,999. During 1968-1993, family income was bottom coded at $1, but after 1994 the definition allows for negative family income of -$999,999 from business or farm losses.

1970's and 1980's in Ziliak et al. (2011), and studies which find rising income volatility over the past 20 to 30 years (Dahl et al 2011; Gottschalk and Moffitt 2009; Hardy and Ziliak 2014) . Table 1 provides summary statistics for income, income volatility, education, gender, age, and race. Columns 3 and 4, "After Restrictions – Main," depicts the characteristics of the main analysis sample which retains family-offspring observations with at least 15 childhood observations between birth and age 16. Mean volatility is 0.623, and the families are relatively advantaged economically, with average family income of $69,011 in 2006 dollars. Almost 70% of the adult children have acquired education beyond high school, 32% of children in the sample have a father with a college degree, and 23% have a mother with a college degree. Approximately 80% of the children grew up in households where parents were continuously married. In a comparison of the PSID sample before imposing sample restrictions (columns 1 and 2 "Before Restrictions") and the main analysis sample, small differences emerge. After restrictions, the sample is slightly younger, less racially diverse, with higher educational attainment among parents and higher income volatility levels.

[Table 1] [Figure 1]

Results

The regression results are reported in Tables 2-6. I demean average log family income and volatility during childhood, transforming γ in Eq. (8) into estimates evaluated at the mean level of permanent family income within the PSID sample. Interactions of volatility with family income test the separability of these measures. Income IGE models are summarized in Table 2 and include controls for transitory volatility. The results for educational attainment in Tables 3-6

are organized by the measure, transitory or total volatility, so as to check the sensitivity of the results to alternative measurement techniques.

[Table 2]

Adult Income

I estimate income IGE models in columns 1-6 of Table 2, with controls for transitory volatility in columns 3-6. These estimates of the association between parents' income (income during childhood) and offspring adult income are meant to at once test the association between childhood income volatility and income in adulthood, while also confirming that the PSID intergenerational sample yields income elasticities consistent with those in the mobility literature. The results suggest that income volatility has no descriptive link to income mobility, and that family economic background, as proxied by permanent income during childhood between birth and age 16 (Table 2 row 1), exhibits a statistically significant income IGE between 0.441 and 0.498. The intergenerational income elasticities and educational attainment models are not meant for causal interpretation, though the income IGE's in columns 2, 4, and 6 include a richer set of demographic controls. The children of one or more parents who attended college are predicted to have higher adult income than children from homes with lesser-educated parents, and black children are less likely to have higher income in adulthood than counterparts of other races/ethnicities (white race is the omitted category). Gender, number of siblings, parents' marital status, and other race/ethnicity have no independent, statistically significant association to adult income within the IGE models, though this changes as the adult outcomes of interest move to educational attainment.

[Table 3]

The link between volatility and adult income could be diminished by the heterogeneity of occupational choices and greater historical variance of earnings observed among college educated workers, in contrast to those with lower education and fewer employment opportunities (Polachek 2008). This is consistent with findings reported below, where a modest association between volatility and educational attainment occurs.

Adult Educational Attainment

In Table 3, I test the association between exposure to transitory income volatility during childhood and both the likelihood of high school dropout and post secondary educational attainment. Transitory volatility during childhood is associated with a statistically insignificant higher likelihood of dropout. A negative relationship to dropout emerges for females, persons with at least 1 college educated parent, and persons from relatively higher income families. There is stronger support for an association between volatility exposure during childhood and education beyond high school. The last two columns of Table 3 depict these results. Here, a one-unit increase in transitory volatility is associated with a 4-5% decrease in the likelihood of post secondary educational attainment. Permanent family income (row 1), measured in log points, is the strongest positive correlate of post high school education, ranging from 0.137 to 0.164. Consistent with the estimates for dropout, females and children of at least 1 college educated parent are predicted to have higher education attainment. Parents' marital status is a positive correlate of post high school attainment, whereas it exhibits no predictive power for high school dropout.

[Table 4]

Table 4 examines high school dropout and post secondary education attainment using the percent change measure of total volatility. A one-year increase in the number of 25% + income shifts is associated with a less than 1% increase in the likelihood of dropout, statistically significant at the 95% confidence level. A one-year increase in 25% + income shifts experienced during childhood is associated with a 1% lower likelihood of post high school educational attainment, also significant at the 95% confidence level. The demographic correlates of both dropout and post high school educational attainment are generally robust to the measure of volatility specified, though permanent income appears to have a larger role and volatility a smaller one in explaining post high school attainment in the total volatility model (Table 4) relative to the transitory model (Table 3).

Income Volatility and Educational Attainment across the Income Distribution

In Tables 5-6, intergenerational education outcomes are examined based upon where mean parental family income lies within the distribution of incomes over ages 0-16 for their children. The families are divided into three groups: bottom 33%, 34-66%, and top 33%. For families with children, mean income among the bottom 33% is approximately $39,000, $59,000 between percentiles 34 and 66, and $93,000 among families in the top 33% of income. Table 5 directly compares the association between volatility (transitory, 25% + total) and high school dropout across the distribution. Table 6 conducts the same test for post high school educational attainment.

[Table 5]

Across the income distribution, the association between volatility exposure and post secondary educational attainment among young adults from households between percentiles 33

and 66 is statistically significant and larger than estimates for young adults from the bottom 33%, the top 33%, or at the mean. In panel A of Table 6, a 1 unit increase in transitory volatility among young adults from families in the middle third of the income distribution is associated with a 10% lowered likelihood of post secondary educational attainment, significant at the 90% confidence level. The results in Tables 5-6 are robust to the exclusion of controls for parental education, which appear to strongly predict dropout and post secondary education across the income distribution. An insignificant association emerges between income volatility and dropout (Table 5). Similarly, no volatility-education association emerges among higher income families, consistent with previous studies and the descriptive intergenerational model in Eq. (7). The fact that no statistically significant volatility-education link emerges between lower income families may still be consistent with the model, particularly if children from moderate income families fall outside the eligibility requirements of grants and subsidies for post-high school education. With cell sizes of roughly 300, it could also be a consequence of efficiency limitations due to relatively small samples.

[Table 6]

In summary, the results suggest a statistically significant association between volatility exposure and lower educational attainment. Consistent relationships also emerge with permanent income, race, gender, parents' education, and parents' marital status. Assessing the importance of these results is challenging, particularly with respect to the valuation of unit changes to demeaned, residualized transitory income volatility. In an effort to improve understanding of the results, I standardize coefficients and evaluate standard deviation changes to explanatory income volatility covariates:

$$\% \Delta \text{ Educational Outcome} = (\sigma_{\text{volatility}}) \times (\hat{\beta}_{volatility}), \quad (10)$$

where $\sigma_{\text{volatility}}$ denotes the standard deviation of income volatility and $\hat{\beta}$ denotes the estimated volatility coefficient of interest. I automate this transformation of the regression coefficients using the Stata procedure constructed by Long and Freese (2005). Using the transformation, a 1 standard deviation increase in transitory volatility, 0.541, is associated with a 2-3% lower likelihood of educational attainment beyond high school (Table 3). A 1 standard deviation increase in transitory volatility among children from the middle 33% of the family income distribution translates to a 5% lower likelihood of post secondary attainment (Table 6). Interestingly, the transformed results are generally equivalent across both transitory and total definitions of volatility. The use of standard deviations allows for comparison across explanatory variables often considered in discussions of socio-economic mobility, such as permanent income. For example, a standard deviation increase in permanent income is associated with a 2% decline in dropout chance in models using the transitory volatility measure, compared to a 1% increase in dropout chance from a standard deviation increase in 25% + total volatility (Table 4). A 1 standard deviation increase in permanent income is associated with a 7 to 8% increase in the likelihood of post secondary educational attainment in transitory models (Table 3), implying the relationship to post secondary attainment from a standard deviation increase in volatility is 29 to 36% of the magnitude of the relationship from a standard deviation increase in permanent income.

Lower income and volatile income carry an association with educational attainment overall, one which appears stronger for post secondary attainment. This may be due to differences underlying the post secondary attainment decision versus completing publicly

provided K-12 education, along with sample high school dropout rates of 5% that are relatively low. If a true causal effect lies within these estimates, some consequences are worth briefly considering. Dropouts experience higher rates of unemployment, have lower family income and earnings, and are more likely to engage in criminal activity (Blank 2008; Haskins et al. 2009; Hauser et al. 2000; Lochner 2005) than their more educated counterparts. Prospects for workers lacking post high school training are also deteriorating, as they increasingly confront a "hollowed-out" labor market with fewer opportunities for middle-skill workers compared to the 1960's, 1970's, or 1980's (Jaimovich and Siu 2012).

With the economic mobility consequences of education in mind, the estimates across the income distribution concur with related studies on parental job loss and children's education, which find larger negative estimates for adults from the bottom half of the socio-economic spectrum (Johnson et al. 2012; Page et al. 2009). This negative association occurs alongside estimated college graduation rates of 11% among young adults from the bottom income quintile to 25% in the middle income quintile of the PSID (Haskins et al. 2009). In other words, lower baseline graduation rates may raise the importance of income volatility and its negative association to adult education outcomes among low and moderate income households. The noticeably larger association among moderate to middle income offspring merits attention, as these families may face important tradeoffs that drive investment decisions in their children. In most instances they do not qualify for federal grants or many of the school-based financial grant programs targeted to children from poor families (Haskins et al. 2009).

Such findings across the income distribution carry important implications, particularly in spite of sample sizes around 350. Efficiency issues may mask larger negative relationships

between volatility exposure and educational attainment, particularly within the bottom 33%, and future work would benefit from data that more completely accounts for lower socio-economic status households.[4] However, the SRC sample of the PSID seems an appropriate beginning point for this inquiry as it is among the preferred data sources in studies of both income mobility and income volatility. Still, the SRC is not without flaws, including attrition bias. PSID attritors are less educated, have lower earnings, and are less likely to be married (Fitzgerald et al. 1998). Such a population likely has higher income and earnings volatility (Ziliak et al. 2011), which could attenuate the results.

Conclusion

To estimate an intergenerational model with family income volatility, I link parents and offspring in the PSID between 1970 and 2007. The purpose of this is to identify what, if any, patterns emerge for adults who grow up with volatile family income as a child. Evaluated at the mean, where family income is roughly $70,000, volatility is associated with lower educational attainment in adulthood, but the link is moderate at best and smaller than the permanent income-educational attainment association. For example, a 1 standard deviation increase in 25% + total volatility is related to a 1% increase in dropout likelihood, while a 1 standard deviation increase in transitory volatility is associated with a 2-3% lower likelihood of post high school education. Among moderate income households the association to adult education is larger, as a 1 deviation increase in transitory volatility is associated with a roughly 5% lower likelihood of education beyond high school. The empirical approach taken accounts for several often-mentioned culprits

[4] The SEO sample of the PSID or the 1979 National Longitudinal Survey of Youth, for example, might provide a richer intergenerational file of low-income families, though these data come with their own tradeoffs.

of economic hardship and instability, including family income, parental education, and parental marital status (Cancian and Reed 2001). This is nonetheless a descriptive estimate holding across model specifications and omitting a range of causal factors likely correlated with both intergenerational mobility and income volatility (Mason 2007). Future work could assess how recent volatility and public policies relate to measures of academic achievement, health, and socio-emotional well-being during childhood using data on low-income families. Such indicators are precursors to adult socio-economic outcomes (Cunha et al. 2005; Mazumder and Davis 2012).

The findings are consistent with a descriptive model in which risk aversion, credit constraints faced by parents, and the persistence of income shocks justify inclusion of both first and second income moments. If the baseline results and estimates from across the income distribution reflect a causal channel, shocks may be more harmful for adults from lower and moderate income families with higher volatility. Today, this would include prospective students from households affected by high unemployment and poverty during the Great recession. Policy responses include the continued provision of low interest loans, grants, and affordable options for educating college-bound children, including two-year colleges. Such a response is helpful if education is constrained by affordability. If, instead, income shocks during early childhood negatively impact the *early* human capital investments of parents, public policies subsidizing higher education may intervene too late. Underinvestment in human capital due to income shocks during childhood may leave some capable students without the skills to pursue education and training beyond high school.

Sample Size	1,366		1,070	

Notes: Restriction is condition that observations contain data for 15 of 16 childhood years. Income is topcoded at 1% and bottomcoded at $1. Adulthood refers to offspring age 25 or older. Childhood refers to offspring age 16 or younger. Age for parents and offspring is the highest reported value. Married is continuous marital status.

Robust standard errors in parentheses. ** p<0.01, * p<0.05, † p<0.10. Coefficients for age not shown. F-statistics tests joint significance of Transitory $Volatility_{0-16}$ and $Income_{0-16} \times$Transitory $Vol_{0-16.}$ Intergenerational income elasticities include order 4 polynomial of offspring age normalized to age 40, as well as normalized offspring age interacted with income during childhood (parents' income), also not shown. Transitory $Volatility_{0-16}$ uses the residual from regressing income on an age quartic. Adult offspring income (dependent variable), $Income_{0-16}$, and Transitory $Volatility_{0-16}$ are constructed using log of mean family income from age 0–16.
